Comparative study of the autumn migration of Marsh Harriers (*Circus aeruginosus*) at three sites of the central Mediterranean

Both during spring and autumn migration substantial numbers of Marsh Harriers (*Circus aeruginosus*) cross the central Mediterranean (GIORDANO 1991, AGOSTINI & LOGOZZO 2000, AGOSTINI 2001a, 2001b, CORSO et al. 2001). In this area the greatest concentration occurs at the Straits of Messina (between Sicily and continental Italy) during spring (max. 3074 individuals counted in 2000; CORSO et al. 2001). In this study, observations were made on the autumn migration of this species at three sites of the Central Mediterranean where notable concentrations of Accipitriformes are recorded each season: the Circeo promontory (CORBI et al. 1999) and the islands of Malta (BEAMAN & GALEA 1974) and Maretitimo (western Sicily, AGOSTINI et al. 2000). The aim was to investigate the routes used by the Marsh Harrier in this area, by comparing the variations of the migratory flow and the proportion of birds belonging to different age and sex classes recorded at each site, to verify the tendency of this species to migrate on a broad front undertaking long crossings of water using powered flight (KERLINGER 1989).

**Study areas and methods**

Observations were made from 15 to 29 September 2000, each day from 9.00 h CET until the dusk, aided with telescope and binocular. The Circeo promontory is located in the southernmost point of the Pianura Pontina reaching 541 m. a.s.l. (Fig.1). The observation post was located along its southern slope and was chosen to detect the direction of birds leaving the promontory. Here no monitoring was made on 20 September because of
heavy rainfalls. Maretimo is a mountainous island (12 km²), about 30 km off western Sicily and 20 km west of the islands of Levanzo and Favignana (Fig. 1). This island is located at the narrowest point of the central Mediterranean, about 130 km NE of the Cap Bon peninsula (Tunisia). Monte Falcone is its highest relief, reaching 686 m. The observation post was located at the altitude of c. 500 m. To date, on this site, observations were made between the end of August and the beginning of September 1997 and 1998 when the greatest concentration of Black Kites (Milvus migrans) and Egyptian Vultures (Neophron percnopterus) through Italy was recorded during post-reproductive movements (Agostini et al. 2000) while only some tens of Marsh Harriers were counted. During spring migration hundreds of Marsh Harriers concentrate on this island (Agostini & Logozzo 1998, Agostini 2001 a, b). The Maltese Islands are situated about 90 km south of Sicily and 335 km north of Libya (Fig. 1). Raptors concentrate along the cliffs on the western side of the Island of Malta (Beamant & Galea 1974). The observation post was situated in this area, on one of the highest points of the island (250 m a.s.l.).

It was possible to determine the age and sex of 552 birds by observation of their plumage (Forssman 1999). The total of males, females and juveniles was derived at each site by multiplying their proportions in the sample of identified individuals, following the method used by Kjellen (1992) in his study on the autumn migration of raptors at the Falsterbo peninsula (Sweden). In particular, to exclude a bias due to the better identification of adult males, the proportion of females and juveniles was estimated dividing unidentified individuals of the group female/juvenile between the two age groups according to their proportion among the identified birds (see also Agostini & Logozzo 2000).

Results and Discussion

At the Circeo promontory a total of 337 Marsh Harriers was counted and more than 80% of them were seen in 5 days (Fig. 2). According to their proportions among aged individuals it has been pos-
sible to estimate the passage of 140 (41.5%) juveniles while, among adults, females outnumbered males (Table; $\chi^2 = 22.1$, df. = 1, $p < 0.001$). Marsh Harriers showed a strong tendency to undertake the water-crossing: they left the coast flying south, heading apparently towards western Sicily via the Ponzone Islands. Over the island of Maretto a total of 220 Marsh Harriers was recorded with about 50% in two days (19 and 24 September, Fig. 2) and also at this site, among adults, females outnumbered males (Table; $\chi^2 = 21.7$, df. = 1, $p < 0.001$). However, by comparing daily variation in

the migratory flows it is possible to note a lack of correspondence between Circeo and Maretto (Fig. 2). Over the island of Malta 416 Marsh Harriers were seen with an evident peak comprising 191 birds on 23 September. At this site, mostly juveniles were recorded and, among adults, the difference between males and females was not significant (Table). These results confirm the strong tendency of this species to migrate on a broad front carrying out long powered flight over water (Kerlinger 1989). For this reason, differently from other raptors using mostly soaring flight over land during migration, concentrations of thousands of Marsh Harriers rarely occur (Kerlinger 1989, Zalles & Bildstein 2000) although 51,000–74,000 pairs breed in Europe (mostly in Russia, Poland and Ukraine; Ferguson-Lees et al. 2001). Probably the hundreds of birds recorded in our study belong to populations breeding in eastern Europe moving along parallel NE-SW directions.

This flight direction agrees with that recorded by radar among harriers leaving the coast of southern Spain (Meyer et al. 2000). Perhaps the migratory flow observed over Maretìmomo is correlated with that observed over Capri (Jonzén & Pettersson 1999) where a total of 134 and 186 birds were seen in 1994 and 1995, respectively, leaving the coast towards SW. Moreover, birds concentrating over Malta could be those observed along the Calabrian Apennines (Southern continental Italy; Agostini & Logozzo 1997, 2000), located NE of the island. Finally, Marsh Harriers undertaking the crossing of the Tyrrenian Sea from the Circeo promontory apparently towards western Sicily, probably deviate SW flying directly towards Tunisia via the Ponziane Islands. On the contrary Maretìmomo, as in spring (Agostini 2001 a, b), should attract birds crossing the Channel of Sicily stressing a correspondence with the variation of the migratory flow recorded at Cìrceo.

Acknowledgements: This research has been partially made within the activities of the Stazione di Indennamento di Palermo, funded by the Assessorato Agricoltura e Foreste of the Regione Siciliana. We wish to thank Bruno Massa for his useful comments on a first draft of the manuscript and the Aeronautica Militare Italiana for the permission to entry in a military zone.

Zusammenfassung

Vergleichende Studie zum Herbstzug von Rohrweihen (Circus aeruginosus) an drei Beobachtungsplätzen im zentralen Mittelmeerraum.
